Type: **Invited talk (30 min + 5 min discussion)**

## Structural evolution of layered H<sub>2</sub>V<sub>3</sub>O<sub>8</sub> high-capacity lithium storing cathode

*Monday, 4 December 2023 13:05 (35 minutes)*

V-based oxides are attracting much interest as promising next-generation electrodes due to the vast resources in the Earth's crust, their unique open structures for fast diffusion with outstanding electrochemical properties and various oxidation redox couples. A recent review has debated if they "will become the future choice for ion-metal batteries".[1] H<sub>2</sub>V<sub>3</sub>O<sub>8</sub> allows reversible two-electron transfer during electrochemical lithium cycling, yielding a high capacity of 378 mAh g<sup>-1</sup>. Aimed at providing insights into the lithium storage mechanism, we employed high-resolution synchrotron X-ray and neutron diffraction to accurately describe the crystal structures of both pristine and lithiated H<sub>2</sub>V<sub>3</sub>O<sub>8</sub>. [2] Easy hydrogen-bonding switch of structural water upon lithium intercalation not only allows better accommodation of intercalated lithium ions but also enhances Li-ion mobility in the crystal host, as evidenced by MAS-NMR spectroscopy. The hydrogen bonds mitigate the volume change of vanadium layers during Li de/intercalation, resulting in improved long-term structural stability. This study suggests that other hydrated oxides may be good candidates as electrode materials not only in implemented Li technology but also emerging rechargeable post-lithium metal-ion batteries.
