# Diffusion of iron in the near-surface region of magnetite (001)

*Monday 17 September 2018 12:00 (15 minutes)*

The mobility of Fe in magnetite is a key ingredient towards a better understanding of its defect structure and resulting properties. For nanoparticles, which find a range of applications in medicine, spintronics, material science and catalysis, the near-surface is particularly important. Recent scanning tunnelling microscopy (STM) and low energy electron diffraction (LEED) studies of the $(\sqrt{2}\times\sqrt{2})$R45° reconstructed (001) surface suggested a subsurface vacancy stabilisation model for this surface, later proved by surface x-ray diffraction (SXRD) [1,2]. Low energy electron microscopy (LEEM) experiments under catalytic conditions showed a regrowth process of $Fe_3O_4$-layers on (001) surfaces [3]. These results point towards an interesting interplay between cation vacancy formation and diffusion.

We present the results of iron exchange at the interface between $^{57}Fe_3O_4$ thin-films and a $Fe_3O_4$ (001) substrate after ultra high vacuum annealing at multiple temperatures. By exploiting the scattering length variation of $^{57}$Fe and natural Fe, its interdiffusion across the film-substrate interface is characterized by neutron reflectometry at MARIA at MLZ [4].
The results on growth and diffusion are complemented by x-ray reflectometry data.
